3.8	Low Level Built in Functions	32
3.9	Types	33

Vyper is an **experimental**, contract-oriented, pythonic programming language that targets the [Ethereum Virtual Machine \(EVM\)](#)

Principles and Goals

- **Security:** It should be possible and natural to build secure smart-contracts in Vyper.
- **Language and compiler simplicity:** The language and the compiler implementation should strive to be simple.
- **Auditability:** Vyper code should be maximally human-readable. Furthermore, it should be maximally difficult to write misleading code. Simplicity for the reader is more important than simplicity for the writer, and simplicity for readers with low prior experience with Vyper (and low prior experience with programming in general) is particularly important.

Because of this Vyper aims to provide the following features:

- **Bounds and overflow checking:** On array accesses as well as on arithmetic level.
- **Support for signed integers and decimal fixed point numbers**
- **Decidability:** It should be possible to compute a precise upper bound for the gas consumption of any function call.
- **Strong typing:** Including support for units (e.g. timestamp, timedelta, seconds, wei, wei per second, meters per second squared).
- **Small and understandable compiler code**
- **Limited support for pure functions:** Anything marked constant is not allowed to change the state.

Following the principles and goals, Vyper **does not** provide the following features:

- **Modifiers:** For example in Solidity you can define a function `foo() mod1 { ... }`, where `mod1` can be defined elsewhere in the code to include a check that is done before execution, a check that is done after execution, some state changes, or possibly other things. Vyper does not have this, because it makes it too easy to write misleading code. `mod1` just looks too innocuous for something that could add arbitrary pre-conditions, post-conditions or state changes. Also, it encourages people to write code where the execution jumps around the file, harming auditability. The usual use case for a modifier is something that performs a single check before execution of a program; our recommendation is to simply inline these checks as asserts.
- **Class inheritance:** Class inheritance requires people to jump between multiple files to understand what a program is doing, and requires people to understand the rules of precedence in case of conflicts (“Which class’s

function ‘X’ is the one that’s actually used?”). Hence, it makes code too complicated to understand which negatively impacts auditability.

- **Inline assembly:** Adding inline assembly would make it no longer possible to search for a variable name in order to find all instances where that variable is read or modified.
- **Function overloading** - This can cause lots of confusion on which function is called at any given time. Thus it’s easier to write misleading code (`foo("hello")` logs “hello” but `foo("hello", "world")` steals you funds). Another problem with function overloading is that it makes the code much harder to search through as you have to keep track on which call refers to which function.
- **Operator overloading:** Operator overloading makes writing misleading code possible. For example “+” could be overloaded so that it executes commands the are not visible at first glance, such as sending funds the user did not want to send.
- **Recursive calling:** Recursive calling makes it impossible to set an upper bound on gas limits, opening the door for gas limit attacks.
- **Infinite-length loops:** Similar to recursive calling, infinite-length loops make it impossible to set an upper bound on gas limits, opening the door for gas limit attacks.
- **Binary fixed point:** Decimal fixed point is better, because any decimal fixed point value written as a literal in code has an exact representation, whereas with binary fixed point approximations are often required (e.g. $(0.2)_{10} = (0.001100110011\dots)_2$, which needs to be truncated), leading to unintuitive results, e.g. in Python $0.3 + 0.3 + 0.3 + 0.1 \neq 1$.

Compatibility-breaking Changelog

- **2018.05.23:** Changed `wei_value` to be `uint256`.
- **2018.04.03:** Changed bytes declaration from `'bytes <= n'` to `'bytes[n]'`.
- **2018.03.27:** Renaming `signed256` to `int256`.
- **2018.03.22:** Add `modifiable` and `static` keywords for external contract calls.
- **2018.03.20:** Renaming `__log__` to `event`.
- **2018.02.22:** Renaming `num` to `int128`, and `num256` to `uint256`.
- **2018.02.13:** Ban functions with `payable` and `constant` decorators.
- **2018.02.12:** Division by `num` returns decimal type.
- **2018.02.09:** Standardize type conversions.
- **2018.02.01:** Functions cannot have the same name as globals.
- **2018.01.27:** Change getter from `get_var` to `var`.
- **2018.01.11:** Change version from 0.0.2 to 0.0.3
- **2018.01.04:** Types need to be specified on assignment ([VIP545](#)).
- **2017.01.02** Change `as_wei_value` to use quotes for units.
- **2017.12.25:** Change name from Viper to Vyper.
- **2017.12.22:** Add `continue` for loops
- **2017.11.29:** `@internal` renamed to `@private`.
- **2017.11.15:** Functions require either `@internal` or `@public` decorators.
- **2017.07.25:** The `def foo() -> num(const): ...` syntax no longer works; you now need to do `def foo() -> num: ...` with a `@constant` decorator on the previous line.
- **2017.07.25:** Functions without a `@payable` decorator now fail when called with nonzero `wei`.

- **2017.07.25:** A function can only call functions that are declared above it (that is, A can call B only if B appears earlier in the code than A does). This was introduced to prevent infinite looping through recursion.

3.1 Installing Vyper

Don't panic if the installation fails. Vyper is still under development and undergoes constant changes. Installation will be much more simplified and optimized after a stable version release.

Take a deep breath, follow the instructions, and please [create an issue](#) if you encounter any errors.

Note: The easiest way to try out the language, experiment with examples, and compile code to `bytecode` or `LLL` is to use the online compiler at <https://vyper.online/>.

3.1.1 Prerequisites

Installing Python 3.6

Vyper can only be built using Python 3.6 and higher. If you are already running Python 3.6, skip to the next section, else follow the instructions here to make sure you have the correct Python version installed, and are using that version.

Ubuntu

16.04 and older

Start by making sure your packages are up-to-date:

```
sudo apt-get update
sudo apt-get -y upgrade
```

Install Python 3.6 and some necessary packages:

```
sudo apt-get install build-essential libssl-dev libffi-dev
wget https://www.python.org/ftp/python/3.6.2/Python-3.6.2.tgz
tar xzf Python-3.6.2.tgz
cd Python-3.6.2/
./configure --prefix /usr/local/lib/python3.6
sudo make
sudo make install
```

16.10 and newer

From Ubuntu 16.10 onwards, the Python 3.6 version is in the *universe* repository.

Run the following commands to install:

```
sudo apt-get update
sudo apt-get install python3.6
```

MacOS

Make sure you have Homebrew installed. If you don't have the *brew* command available on the terminal, follow [these instructions](#) to get Homebrew on your system.

To install Python 3.6, follow the instructions here: [Installing Python 3 on Mac OS X](#)

Also, ensure the following libraries are installed using *brew*:

```
brew install gmp leveldb
```

Creating a virtual environment

It is **strongly recommended** to install Vyper in a **virtual Python environment**, so that new packages installed and dependencies built are strictly contained in your Vyper project and will not alter or affect your other development environment set-up.

To create a new virtual environment for Vyper run the following commands:

```
virtualenv -p python3.6 --no-site-packages ~/vyper-venv
source ~/vyper-venv/bin/activate
```

To find out more about virtual environments, check out: [virtualenv guide](#).

3.1.2 Installation

Again, it is **strongly recommended to install Vyper** in a **virtual Python environment**. This guide assumes you are in a virtual environment containing Python 3.6.

Get the latest version of Vyper by cloning the Github repository, and run the install and test commands:

```
git clone https://github.com/ethereum/vyper.git
cd vyper
make
make test
```

Additionally, you may try to compile an example contract by running:

```
vyper examples/crowdfund.v.py
```

If everything works correctly, you are now able to compile your own smart contracts written in Vyper. However, please keep in mind that Vyper is still experimental and not ready for production!

Note: If you get the error *fatal error: openssl/aes.h: No such file or directory* in the output of *make*, then run *sudo apt-get install libssl-dev*, then run *make* again.

For MacOS users:

Apple has deprecated use of OpenSSL in favor of its own TLS and crypto libraries. This means that you will need to export some OpenSSL settings yourself, before you can install Vyper.

Use the following commands:

```
export CFLAGS="-I$(brew --prefix openssl)/include"
export LDFLAGS="-L$(brew --prefix openssl)/lib"
pip install scrypt
```

Now you can run the install and test commands again:

```
make
make test
```

If you get the error *ld: library not found for -lyaml* in the output of *make*, make sure *libyaml* is installed using *brew info libyaml*. If it is installed, add its location to the compile flags as well:

```
export CFLAGS="-I$(brew --prefix openssl)/include -I$(brew --prefix libyaml)/include"
export LDFLAGS="-L$(brew --prefix openssl)/lib -L$(brew --prefix libyaml)/lib"
```

You can then run *make* and *make test* again.

3.1.3 Docker

A Dockerfile is provided in the master branch of the repository. In order to build a Docker Image please run:

```
docker build https://github.com/ethereum/vyper.git -t vyper:1
docker run -it vyper:1 /bin/bash
```

To ensure that everything works correctly after the installation, please run the test commands and try compiling a contract:

```
make test
vyper examples/crowdfund.v.py
```

3.1.4 Snap

Vyper is published in the snap store. In any of the [supported Linux distros](#), install it with:

```
sudo snap install vyper --edge
```

(Note that this is an experimental and unstable release, at the moment)

3.2 Compiling a Contract

To compile a contract, use:

```
vyper yourFileName.v.py
```

You can also compile to other formats such as ABI using the below format:

```
vyper -f ['abi', 'json', 'bytecode', 'bytecode_runtime', 'ir'] yourFileName.v.py
```

Note: Since `.vy` is not officially a language supported by any syntax highlighters or linters, it is recommended to name your Vyper file ending with `.vy` or optionally `.v.py` in order to have Python syntax highlighting.

An [online compiler](#) is available as well, which lets you experiment with the language without having to install Vyper. The online compiler allows you to compile to `bytecode` and/or `LLL`.

Note: While the vyper version of the online compiler is updated on a regular basis it might be a bit behind the latest version found in the master branch of the repository.

3.3 Structure of a Contract

Contracts in Vyper are contained within files, with each file being one smart-contract. Files in Vyper are similar to classes in object-oriented languages. Each file can contain declarations of *State Variables*, *Functions*, and structure-structs-types.

3.3.1 State Variables

State variables are values which are permanently stored in contract storage.

```
storedData: int128
```

See the [Types](#) section for valid state variable types and visibility-and-getters for possible choices for visibility.

3.3.2 Functions

Functions are the executable units of code within a contract.

```
@public
@payable
def bid(): // Function
    // ...
```

Function-calls can happen internally or externally and have different levels of visibility (visibility-and-getters) towards other contracts. Functions must be decorated with either `@public` or `@private`.

3.3.3 Events

Events may be logged in specially indexed data structures that allow clients, including light clients, to efficiently search for them.

```

Payment: event({amount: int128, arg2: indexed(address)})

total_paid: int128

@public
@payable
def pay():
    self.total_paid += msg.value
    log.Payment(msg.value, msg.sender)

```

Events must be declared before global declarations and function definitions.

3.4 Vyper by Example

3.4.1 Simple Open Auction

As an introductory example of a smart contract written in Vyper, we will begin with a simple open auction contract. As we dive into the code, it is important to remember that all Vyper syntax is valid Python3 syntax, however not all Python3 functionality is available in Vyper.

In this contract, we will be looking at a simple open auction contract where participants can submit bids during a limited time period. When the auction period ends, a predetermined beneficiary will receive the amount of the highest bid.

```

1  # Open Auction
2
3  # Auction params
4  # Beneficiary receives money from the highest bidder
5  beneficiary: public(address)
6  auction_start: public(timestamp)
7  auction_end: public(timestamp)
8
9  # Current state of auction
10 highest_bidder: public(address)
11 highest_bid: public(wei_value)
12
13 # Set to true at the end, disallows any change
14 ended: public(bool)
15
16 # Create a simple auction with `_bidding_time`
17 # seconds bidding time on behalf of the
18 # beneficiary address `_beneficiary`.
19 @public
20 def __init__(_beneficiary: address, _bidding_time: timedelta):
21     self.beneficiary = _beneficiary
22     self.auction_start = block.timestamp
23     self.auction_end = self.auction_start + _bidding_time
24
25 # Bid on the auction with the value sent
26 # together with this transaction.

```

(continues on next page)

(continued from previous page)

```
27 # The value will only be refunded if the
28 # auction is not won.
29 @public
30 @payable
31 def bid():
32     # Check if bidding period is over.
33     assert block.timestamp < self.auction_end
34     # Check if bid is high enough
35     assert msg.value > self.highest_bid
36     if not self.highest_bid == 0:
37         # Sends money back to the previous highest bidder
38         send(self.highest_bidder, self.highest_bid)
39     self.highest_bidder = msg.sender
40     self.highest_bid = msg.value
41
42
43 # End the auction and send the highest bid
44 # to the beneficiary.
45 @public
46 def end_auction():
47     # It is a good guideline to structure functions that interact
48     # with other contracts (i.e. they call functions or send Ether)
49     # into three phases:
50     # 1. checking conditions
51     # 2. performing actions (potentially changing conditions)
52     # 3. interacting with other contracts
53     # If these phases are mixed up, the other contract could call
54     # back into the current contract and modify the state or cause
55     # effects (Ether payout) to be performed multiple times.
56     # If functions called internally include interaction with external
57     # contracts, they also have to be considered interaction with
58     # external contracts.
59
60     # 1. Conditions
61     # Check if auction endtime has been reached
62     assert block.timestamp >= self.auction_end
63     # Check if this function has already been called
64     assert not self.ended
65
66     # 2. Effects
67     self.ended = True
68
69     # 3. Interaction
70     send(self.beneficiary, self.highest_bid)
```

As you can see, this example only has a constructor, two methods to call, and a few variables to manage the contract state. Believe it or not, this is all we need for a basic implementation of an auction smart contract.

Let's get started!

```
# Auction params
# Beneficiary receives money from the highest bidder
beneficiary: public(address)
auction_start: public(timestamp)
auction_end: public(timestamp)

# Current state of auction
```

(continues on next page)

(continued from previous page)

```

highest_bidder: public(address)
highest_bid: public(wei_value)

# Set to true at the end, disallows any change
ended: public(bool)

```

We begin by declaring a few variables to keep track of our contract state. We initialize a global variable `beneficiary` by calling `public` on the datatype `address`. The beneficiary will be the receiver of money from the highest bidder. We also initialize the variables `auction_start` and `auction_end` with the datatype `timestamp` to manage the open auction period and `highest_bid` with datatype `wei_value`, the smallest denomination of ether, to manage auction state. The variable `ended` is a boolean to determine whether the auction is officially over.

You may notice all of the variables being passed into the `public` function. By declaring the variable `public`, the variable is callable by external contracts. Initializing the variables without the `public` function defaults to a private declaration and thus only accessible to methods within the same contract. The `public` function additionally creates a ‘getter’ function for the variable, accessible with a call such as `self.get_beneficiary(some_address)`.

Now, the constructor.

The contract is initialized with two arguments: `_beneficiary` of type `address` and `_bidding_time` with type `timedelta`, the time difference between the start and end of the auction. We then store these two pieces of information into the contract variables `self.beneficiary` and `self.auction_end`. Notice that we have access to the current time by calling `block.timestamp`. `block` is an object available within any Vyper contract and provides information about the block at the time of calling. Similar to `block`, another important object available to us within the contract is `msg`, which provides information on the method caller as we will soon see.

With initial setup out of the way, let's look at how our users can make bids.

The `@payable` decorator will allow a user to send some ether to the contract in order to call the decorated method. In this case, a user wanting to make a bid would call the `bid()` method while sending an amount equal to their desired bid (not including gas fees). When calling any method within a contract, we are provided with a built-in variable `msg` and we can access the public address of any method caller with `msg.sender`. Similarly, the amount of ether a user sends can be accessed by calling `msg.value`.

Warning: `msg.sender` will change between internal function calls so that if you're calling a function from the outside, it's correct for the first function call. But then, for the function calls after, `msg.sender` will reference the contract itself as opposed to the sender of the transaction.

Here, we first check whether the current time is before the auction's end time using the `assert` function which takes any boolean statement. We also check to see if the new bid is greater than the highest bid. If the two `assert` statements pass, we can safely continue to the next lines; otherwise, the `bid()` method will throw an error and revert the transaction. If the two `assert` statements and the check that the previous bid is not equal to zero pass, we can safely conclude that we have a valid new highest bid. We will send back the previous `highest_bid` to the previous `highest_bidder` and set our new `highest_bid` and `highest_bidder`.

With the `auction_end()` method, we check whether our current time is past the `auction_end` time we set upon initialization of the contract. We also check that `self.ended` had not previously been set to `True`. We do this to prevent any calls to the method if the auction had already ended, which could potentially be malicious if the check had not been made. We then officially end the auction by setting `self.ended` to `True` and sending the highest bid amount to the beneficiary.

And there you have it - an open auction contract. Of course, this is a simplified example with barebones functionality and can be improved. Hopefully, this has provided some insight to the possibilities of Vyper. As we move on to exploring more complex examples, we will encounter more design patterns and features of the Vyper language.

And of course, no smart contract tutorial is complete without a note on security.

Note: It's always important to keep security in mind when designing a smart contract. As any application becomes more complex, the greater the potential for introducing new risks. Thus, it's always good practice to keep contracts as readable and simple as possible.

Whenever you're ready, let's turn it up a notch in the next example.

3.4.2 Safe Remote Purchases

In this example, we have an escrow contract implementing a system for a trustless transaction between a buyer and a seller. In this system, a seller posts an item for sale and makes a deposit to the contract of twice the item's `value`. At this moment, the contract has a balance of $2 * \text{value}$. The seller can reclaim the deposit and close the sale as long as a buyer has not yet made a purchase. If a buyer is interested in making a purchase, they would make a payment and submit an equal amount for deposit (totaling $2 * \text{value}$) into the contract and locking the contract from further modification. At this moment, the contract has a balance of $4 * \text{value}$ and the seller would send the item to buyer. Upon the buyer's receipt of the item, the buyer will mark the item as received in the contract, thereby returning the buyer's deposit (not payment), releasing the remaining funds to the seller, and completing the transaction.

There are certainly others ways of designing a secure escrow system with less overhead for both the buyer and seller, but for the purpose of this example, we want to explore one way how an escrow system can be implemented trustlessly.

Let's go!

```
1 #Safe Remote Purchase
2 #Originally from
3 #https://github.com/ethereum/solidity/blob/develop/docs/solidity-by-example.rst
4 #ported to vyper and optimized
5
6 #Rundown of the transaction:
7 #1. Seller posts item for sale and posts safety deposit of double the item value.
8 # Balance is 2*value.
9 #(1.1. Seller can reclaim deposit and close the sale as long as nothing was purchased.
10 ↪)
11 #2. Buyer purchases item (value) plus posts an additional safety deposit (Item value).
12 # Balance is 4*value.
13 #3. Seller ships item.
14 #4. Buyer confirms receiving the item. Buyer's deposit (value) is returned.
15 #Seller's deposit (2*value) + items value is returned. Balance is 0.
16
17 value: public(wei_value) #Value of the item
18 seller: public(address)
19 buyer: public(address)
20 unlocked: public(bool)
21 #@constant
22 #def unlocked() -> bool: #Is a refund possible for the seller?
23 #     return (self.balance == self.value*2)
24
25 @public
26 @payable
27 def __init__():
28     assert (msg.value % 2) == 0
29     self.value = msg.value / 2 #The seller initializes the contract by
30     #posting a safety deposit of 2*value of the item up for sale.
31     self.seller = msg.sender
```

(continues on next page)

(continued from previous page)

```

31     self.unlocked = True
32
33 @public
34 def abort():
35     assert self.unlocked #Is the contract still refundable?
36     assert msg.sender == self.seller #Only the seller can refund
37         # his deposit before any buyer purchases the item.
38     selfdestruct(self.seller) #Refunds the seller and deletes the contract.
39
40 @public
41 @payable
42 def purchase():
43     assert self.unlocked #Is the contract still open (is the item still up for sale)?
44     assert msg.value == (2 * self.value) #Is the deposit the correct value?
45     self.buyer = msg.sender
46     self.unlocked = False
47
48 @public
49 def received():
50     assert not self.unlocked #Is the item already purchased and pending confirmation
51         # from the buyer?
52     assert msg.sender == self.buyer
53     send(self.buyer, self.value) #Return the buyer's deposit (=value) to the buyer.
54     selfdestruct(self.seller) #Return the seller's deposit (=2*value)
55         # and the purchase price (=value) to the seller.

```

This is also a moderately short contract, however a little more complex in logic. Let's break down this contract bit by bit.

```

value: public(wei_value) #Value of the item
seller: public(address)
buyer: public(address)
unlocked: public(bool)

```

Like the other contracts, we begin by declaring our global variables public with their respective datatypes. Remember that the public function allows the variables to be *readable* by an external caller, but not *writable*.

With a @payable decorator on the constructor, the contract creator will be required to make an initial deposit equal to twice the item's value to initialize the contract, which will be later returned. This is in addition to the gas fees needed to deploy the contract on the blockchain, which is not returned. We assert that the deposit is divisible by 2 to ensure that the seller deposited a valid amount. The constructor stores the item's value in the contract variable self.value and saves the contract creator into self.seller. The contract variable self.unlocked is initialized to True.

The abort() method is a method only callable by the seller and while the contract is still unlocked—meaning it is callable only prior to any buyer making a purchase. As we will see in the purchase() method that when a buyer calls the purchase() method and sends a valid amount to the contract, the contract will be locked and the seller will no longer be able to call abort().

When the seller calls abort() and if the assert statements pass, the contract will call the selfdestruct() function and refunds the seller and subsequently destroys the contract.

Like the constructor, the purchase() method has a @payable decorator, meaning it can be called with a payment. For the buyer to make a valid purchase, we must first assert that the contract's unlocked property is True and that the amount sent is equal to twice the item's value. We then set the buyer to the msg.sender and lock the contract. At this point, the contract has a balance equal to 4 times the item value and the seller must send the item to the buyer.

Finally, upon the buyer's receipt of the item, the buyer can confirm their receipt by calling the received() method

to distribute the funds as intended—where the seller receives 3/4 of the contract balance and the buyer receives 1/4.

By calling `received()`, we begin by checking that the contract is indeed locked, ensuring that a buyer had previously paid. We also ensure that this method is only callable by the buyer. If these two `assert` statements pass, we refund the buyer their initial deposit and send the seller the remaining funds. The contract is finally destroyed and the transaction is complete.

Whenever we're ready, let's move on to the next example.

3.4.3 Crowdfund

Now, let's explore a straightforward example for a crowdfunding contract where prospective participants can contribute funds to a campaign. If the total contribution to the campaign reaches or surpasses a predetermined funding goal, the funds will be sent to the beneficiary at the end of the campaign deadline. Participants will be refunded their respective contributions if the total funding does not reach its target goal.

```

1  #Setup private variables (only callable from within the contract)
2  funders: {sender: address, value: wei_value}[int128]
3  nextFunderIndex: int128
4  beneficiary: address
5  deadline: timestamp
6  goal: wei_value
7  refundIndex: int128
8  timelimit: timedelta
9
10 # Setup global variables
11 @public
12 def __init__(_beneficiary: address, _goal: wei_value, _timelimit: timedelta):
13     self.beneficiary = _beneficiary
14     self.deadline = block.timestamp + _timelimit
15     self.timelimit = _timelimit
16     self.goal = _goal
17
18 # Participate in this crowdfunding campaign
19 @public
20 @payable
21 def participate():
22     assert block.timestamp < self.deadline
23     nfi: int128 = self.nextFunderIndex
24     self.funders[nfi] = {sender: msg.sender, value: msg.value}
25     self.nextFunderIndex = nfi + 1
26
27 # Enough money was raised! Send funds to the beneficiary
28 @public
29 def finalize():
30     assert block.timestamp >= self.deadline and self.balance >= self.goal
31     selfdestruct(self.beneficiary)
32
33 # Not enough money was raised! Refund everyone (max 30 people at a time
34 # to avoid gas limit issues)
35 @public
36 def refund():
37     assert block.timestamp >= self.deadline and self.balance < self.goal
38     ind: int128 = self.refundIndex
39     for i in range(ind, ind + 30):
40         if i >= self.nextFunderIndex:
41             self.refundIndex = self.nextFunderIndex

```

(continues on next page)

(continued from previous page)

```

42     return
43     send(self.funders[i].sender, self.funders[i].value)
44     self.funders[i] = None
45     self.refundIndex = ind + 30

```

Most of this code should be relatively straightforward after going through our previous examples. Let's dive right in.

```

#Setup private variables (only callable from within the contract)
funders: {sender: address, value: wei_value}[int128]
nextFunderIndex: int128
beneficiary: address
deadline: timestamp
goal: wei_value
refundIndex: int128
timelimit: timedelta

```

Like other examples, we begin by initiating our variables - except this time, we're not calling them with the `public` function. Variables initiated this way are, by default, private.

..note :: Unlike the existence of the function `public()`, there is no equivalent `private()` function. Variables simply default to private if initiated without the `public()` function.

The `funders` variable is initiated as a mapping where the key is a number, and the value is a struct representing the contribution of each participant. This struct contains each participant's public address and their respective value contributed to the fund. The key corresponding to each struct in the mapping will be represented by the variable `nextFunderIndex` which is incremented with each additional contributing participant. Variables initialized with the `int128` type without an explicit value, such as `nextFunderIndex`, defaults to 0. The `beneficiary` will be the final receiver of the funds once the crowdfunding period is over—as determined by the `deadline` and `timelimit` variables. The `goal` variable is the target total contribution of all participants. `refundIndex` is a variable for bookkeeping purposes in order to avoid gas limit issues in the scenario of a refund.

Our constructor function takes 3 arguments: the beneficiary's address, the goal in wei value, and the difference in time from start to finish of the crowdfunding. We initialize the arguments as contract variables with their corresponding names. Additionally, a `self.deadline` is initialized to set a definitive end time for the crowdfunding period.

Now lets take a look at how a person can participate in the crowdfunding.

Once again, we see the `@payable` decorator on a method, which allows a person to send some ether along with a call to the method. In this case, the `participate()` method accesses the sender's address with `msg.sender` and the corresponding amount sent with `msg.value`. This information is stored into a struct and then saved into the `funders` mapping with `self.nextFunderIndex` as the key. As more participants are added to the mapping, `self.nextFunderIndex` increments appropriately to properly index each participant.

The `finalize()` method is used to complete the crowdfunding process. However, to complete the crowdfunding, the method first checks to see if the crowdfunding period is over and that the balance has reached/passed its set goal. If those two conditions pass, the contract calls the `selfdestruct()` function and sends the collected funds to the beneficiary.

Note: Notice that we have access to the total amount sent to the contract by calling `self.balance`, a variable we never explicitly set. Similar to `msg` and `block`, `self.balance` is a built-in variable thats available in all Vyper contracts.

We can finalize the campaign if all goes well, but what happens if the crowdfunding campaign isn't successful? We're going to need a way to refund all the participants.

In the `refund()` method, we first check that the crowdfunding period is indeed over and that the total collected

balance is less than the goal with the `assert` statement . If those two conditions pass, we then loop through every participant and call `send()` to send each participant their respective contribution. For the sake of gas limits, we group the number of contributors in batches of 30 and refund them one at a time. Unfortunately, if there's a large number of participants, multiple calls to `refund()` may be necessary.

3.4.4 Voting

In this contract, we will implement a system for participants to vote on a list of proposals. The chairperson of the contract will be able to give each participant the right to vote, and each participant may choose to vote, or delegate their vote to another voter. Finally, a winning proposal will be determined upon calling the `winning_proposals()` method, which iterates through all the proposals and returns the one with the greatest number of votes.

```

1  # Voting with delegation.

153 @constant
154 def winner_name() -> bytes32:
155     return self.proposals[self.winning_proposal()].name
```

As we can see, this is contract of moderate length which we will dissect section by section. Let's begin!

```

# Information about voters
voters: public({
    # weight is accumulated by delegation
    weight: int128,
    # if true, that person already voted (which includes voting by delegating)
    voted: bool,
    # person delegated to
    delegate: address,
    # index of the voted proposal, which is not meaningful unless `voted` is True.
    vote: int128
})[address])

# This is a type for a list of proposals.
proposals: public({
    # short name (up to 32 bytes)
    name: bytes32,
    # int128ber of accumulated votes
    vote_count: int128
})[int128])

voter_count: public(int128)
chairperson: public(address)
int128_proposals: public(int128)

```

The variable `voters` is initialized as a mapping where the key is the voter's public address and the value is a struct describing the voter's properties: `weight`, `voted`, `delegate`, and `vote`, along with their respective datatypes.

Similarly, the `proposals` variable is initialized as a public mapping with `int128` as the key's datatype and a struct to represent each proposal with the properties `name` and `vote_count`. Like our last example, we can access any value by key'ing into the mapping with a number just as one would with an index in an array.

Then, `voter_count` and `chairperson` are initialized as `public` with their respective datatypes.

Let's move onto the constructor.

Warning: Both `msg.sender` and `msg.balance` change between internal function calls so that if you're calling a function from the outside, it's correct for the first function call. But then, for the function calls after, `msg.sender` and `msg.balance` reference the contract itself as opposed to the sender of the transaction.

In the constructor, we hard-coded the contract to accept an array argument of exactly two proposal names of type `bytes32` for the contracts initialization. Because upon initialization, the `__init__()` method is called by the contract creator, we have access to the contract creator's address with `msg.sender` and store it in the contract variable `self.chairperson`. We also initialize the contract variable `self.voter_count` to zero to initially represent the number of votes allowed. This value will be incremented as each participant in the contract is given the right to vote by the method `give_right_to_vote()`, which we will explore next. We loop through the two proposals from the argument and insert them into `proposals` mapping with their respective index in the original array as its key.

Now that the initial setup is done, lets take a look at the functionality.

We need a way to control who has the ability to vote. The method `give_right_to_vote()` is a method callable by only the chairperson by taking a voter address and granting it the right to vote by incrementing the voter's `weight` property. We sequentially check for 3 conditions using `assert`. The `assert not` function will check for falsy boolean values - in this case, we want to know that the voter has not already voted. To represent voting power, we will set their `weight` to 1 and we will keep track of the total number of voters by incrementing `voter_count`.

In the method `delegate`, firstly, we check to see that `msg.sender` has not already voted and secondly, that the

target delegate and the `msg.sender` are not the same. Voters shouldn't be able to delegate votes to themselves. We, then, loop through all the voters to determine whether the person delegate to had further delegated their vote to someone else in order to follow the chain of delegation. We then mark the `msg.sender` as having voted if they delegated their vote. We increment the proposal's `vote_count` directly if the delegate had already voted or increase the delegate's vote `weight` if the delegate has not yet voted.

Now, let's take a look at the logic inside the `vote()` method, which is surprisingly simple. The method takes the key of the proposal in the `proposals` mapping as an argument, check that the method caller had not already voted, sets the voter's `vote` property to the proposal key, and increments the proposals `vote_count` by the voter's `weight`.

With all the basic functionality complete, what's left is simply returning the winning proposal. To do this, we have two methods: `winning_proposal()`, which returns the key of the proposal, and `winner_name()`, returning the name of the proposal. Notice the `@constant` decorator on these two methods. We do this because the two methods only read the blockchain state and do not modify it. Remember, reading the blockchain state is free; modifying the state costs gas. By having the `@constant` decorator, we let the EVM know that this is a read-only function and we benefit by saving gas fees.

The `winning_proposal()` method returns the key of proposal in the `proposals` mapping. We will keep track of greatest number of votes and the winning proposal with the variables `winning_vote_count` and `winning_proposal`, respectively by looping through all the proposals.

And finally, the `winner_name()` method returns the name of the proposal by key'ing into the `proposals` mapping with the return result of the `winning_proposal()` method.

And there you have it - a voting contract. Currently, many transactions are needed to assign the rights to vote to all participants. As an exercise, can we try to optimize this?

Now that we're familiar with basic contracts. Let's step up the difficulty.

3.4.5 Company Stock

This contract is just a tad bit more thorough than the ones we've previously encountered. In this example, we are going to look at a comprehensive contract that manages the holdings of all shares of a company. The contract allows for a person to buy, sell, and transfer shares of a company as well as allowing for the company to pay a person in ether. The company, upon initialization of the contract, holds all shares of the company at first but can sell them all.

Let's get started.

```
1 units: {
2     currency_value: "Currency Value"
3 }
4
5 # Financial events the contract logs
6 Transfer: event({_from: indexed(address), _to: indexed(address), _value:
7     ↳uint256(currency_value)})
8 Buy: event({_buyer: indexed(address), _buy_order: uint256(currency_value)})
9 Sell: event({_seller: indexed(address), _sell_order: uint256(currency_value)})
10 Pay: event({_vendor: indexed(address), _amount: wei_value})
11
12 # Initiate the variables for the company and it's own shares.
13 company: public(address)
14 total_shares: public(uint256(currency_value))
15 price: public(uint256(wei / currency_value))
16
17 # Store a ledger of stockholder holdings.
18 holdings: uint256(currency_value)[address]
19
20 # Set up the company.
```

(continues on next page)

(continued from previous page)

```

20 @public
21 def __init__(_company: address, _total_shares: uint256(currency_value),
22             initial_price: uint256(wei / currency_value) ):
23     assert _total_shares > 0
24     assert initial_price > 0
25
26     self.company = _company
27     self.total_shares = _total_shares
28     self.price = initial_price

108        assert self.cash() >= amount
109
110        # Pay the bill!
111        send(vendor, amount)
112
113        # Log the payment event.
114        log.Pay(vendor, amount)
115
116    # Return the amount in wei that a company has raised in stock offerings.
117    @public
118    @constant
119    def debt() -> wei_value:
120        return (self.total_shares - self.holdings[self.company]) * self.price
121
122    # Return the cash holdings minus the debt of the company.
123    # The share debt or liability only is included here,
124    # but of course all other liabilities can be included.
125    @public
126    @constant
127    def worth() -> wei_value:
128        return self.cash() - self.debt()
```

The contract contains a number of methods that modify the contract state as well as a few ‘getter’ methods to read it. We first declare several events that the contract logs. We then declare our global variables, followed by function definitions.

```

Buy: event({_buyer: indexed(address), _buy_order: uint256(currency_value)})
Sell: event({_seller: indexed(address), _sell_order: uint256(currency_value)})
Pay: event({_vendor: indexed(address), _amount: wei_value})

# Initiate the variables for the company and it's own shares.
company: public(address)
total_shares: public(uint256(currency_value))

```

We initiate the `company` variable to be of type `address` that's `public`. The `total_shares` variable is of type `currency_value`, which in this case represents the total available shares of the company. The `price` variable represents the wei value of a share and `holdings` is a mapping that maps an address to the number of shares the address owns.

In the constructor, we set up the contract to check for valid inputs during the initialization of the contract via the two `assert` statements. If the inputs are valid, the contract variables are set accordingly and the company's address is initialized to hold all shares of the company in the `holdings` mapping.

We will be seeing a few `@constant` decorators in this contract—which is used to decorate methods that simply read the contract state or return a simple calculation on the contract state without modifying it. Remember, reading the blockchain is free, writing on it is not. Since Vyper is a statically typed language, we see an arrow following the definition of the `stock_available()` method, which simply represents the data type which the function is expected to return. In the method, we simply key into `self.holdings` with the company's address and check it's `holdings`.

Now, lets take a look at a method that lets a person buy stock from the company's holding.

The `buy_stock()` method is a `@payable` method which takes an amount of ether sent and calculates the `buy_order` (the stock value equivalence at the time of call). The number of shares is deducted from the company's `holdings` and transferred to the sender's in the `holdings` mapping.

Now that people can buy shares, how do we check someone's holdings?

The `get_holdings()` is another `@constant` method that takes an `address` and returns its corresponding stock holdings by keying into `self.holdings`.

To check the ether balance of the company, we can simply call the getter method `cash()`.

To sell a stock, we have the `sell_stock()` method which takes a number of stocks a person wishes to sell, and sends the equivalent value in ether to the seller's address. We first `assert` that the number of stocks the person wishes to sell is a value greater than 0. We also `assert` to see that the user can only sell as much as the user owns and that the company has enough ether to complete the sale. If all conditions are met, the holdings are deducted from the seller and given to the company. The ethers are then sent to the seller.

A stockholder can also transfer their stock to another stockholder with the `transfer_stock()` method. The method takes a receiver address and the number of shares to send. It first `asserts` that the amount being sent is greater than 0 and `asserts` whether the sender has enough stocks to send. If both conditions are satisfied, the transfer is made.

The company is also allowed to pay out an amount in ether to an address by calling the `pay_bill()` method. This method should only be callable by the company and thus first checks whether the method caller's address matches that of the company. Another important condition to check is that the company has enough funds to pay the amount. If both conditions satisfy, the contract sends its ether to an address.

We can also check how much the company has raised by multiplying the number of shares the company has sold and the price of each share. We can get this value by calling the `debt()` method.

Finally, in this `worth()` method, we can check the worth of a company by subtracting its debt from its ether balance.

This contract has been the most thorough example so far in terms of its functionality and features. Yet despite the thoroughness of such a contract, the logic remained simple. Hopefully, by now, the Vyper language has convinced

you of its capabilities and readability in writing smart contracts.

3.5 Contributing

Help is always appreciated!

To get started, you can try [installing Vyper](#) in order to familiarize yourself with the components of Vyper and the build process. Also, it may be useful to become well-versed at writing smart-contracts in Vyper.

3.5.1 Types of Contributions

In particular, we need help in the following areas:

- Improving the documentation
- Responding to questions from other users on [StackExchange](#) and the [Vyper Gitter](#)
- Suggesting Improvements
- Fixing and responding to [Vyper's GitHub issues](#)

3.5.2 How to Suggest Improvements

To suggest an improvement, please create a Vyper Improvement Proposal (VIP for short) using the [VIP Template](#).

3.5.3 How to Report Issues

To report an issue, please use the [GitHub issues tracker](#). When reporting issues, please mention the following details:

- Which version of Vyper you are using
- What was the source code (if applicable)
- Which platform are you running on
- Your operating system name and version
- Detailed steps to reproduce the issue
- What was the result of the issue
- What the expected behaviour is

Reducing the source code that caused the issue to a bare minimum is always very helpful and sometimes even clarifies a misunderstanding.

3.5.4 Fix Bugs

Find or report bugs at our [issues page](#). Anything tagged with “bug” is open to whoever wants to implement it.

3.5.5 Workflow for Pull Requests

In order to contribute, please fork off of the `master` branch and make your changes there. Your commit messages should detail *why* you made your change in addition to *what* you did (unless it is a tiny change).

If you need to pull in any changes from `master` after making your fork (for example, to resolve potential merge conflicts), please avoid using `git merge` and instead, `git rebase` your branch.

Implement Features

If you are writing a new feature, please ensure you write appropriate Boost test cases and place them under `tests/`.

If you are making a larger change, please consult first with the Gitter channel.

Although we do CI testing, please make sure that the tests pass for supported Python version and ensure that it builds locally before submitting a pull request.

Thank you for your help!

3.6 Frequently Asked Questions

3.6.1 Basic Questions

3.6.2 Advanced Questions

3.7 Built in Functions

Vyper contains a set amount of built in functions that would be timely and/or unachievable to write in Vyper.

3.7.1 Functions

floor

```
def floor(a) -> b:
    """
    :param a: value to round down
    :type a: decimal

    :output b: int128
    """
```

Rounds a decimal down to the nearest integer.

ceil

```
def ceil(a) -> b:
    """
    :param a: value to round up
    :type a: decimal

    :output b: int128
    """
```

Rounds a decimal up to the nearest integer.

convert

```
def convert(a, b) -> c:
    """
    :param a: value to convert
    :type a: either decimal, int128, uint256 or bytes32
    :param b: the destination type to convert to
    :type b: str_literal

    :output c: either decimal, int128, uint256 or bytes32
    """
```

Converts a variable/ literal from one type to another.

as_wei_value

```
def as_wei_value(a, b) -> c:
    """
    :param a: value for the ether unit
    :type a: uint256 or int128 or decimal
    :param b: ether unit name (e.g. ``"wei"``)
    :type b: str_literal

    :output c: wei_value
    """
```

The value of the input number as wei, converted based on the specified unit.

as_unitless_number

```
def as_unitless_number(a) -> b:
    """
    :param a: value to remove units from
    :type a: either decimal or int128

    :output b: either decimal or int128
    """
```

Turns a int128, uint256, decimal with units into one without units (used for assignment and math).

convert

```
def convert(inp, out) -> b:
    """
    :param inp: variable to be converted
    :type inp: type of the variable
    :param out: type to convert (e.g. 'int128', 'uint256', 'decimal', 'bytes32')
    :type out: String

    :output b: converted variable
    """
```

Converts a variable's type.

slice

```
def slice(a, start=b, length=c) -> d:
    """
    :param a: bytes to be sliced
    :type a: either bytes or bytes32
    :param b: start position of the slice
    :type b: int128
    :param c: length of the slice
    :type c: int128

    :output d: bytes
    """
```

Takes a list of bytes and copies, then returns a specified chunk.

len

```
def len(a) -> b:
    """
    :param a: value to get the length of
    :type a: bytes

    :output b: int128
    """
```

Returns the length of a given list of bytes.

concat

```
def concat(a, b, ...) -> c:
    """
    :param a: value to combine
    :type a: bytes
    :param b: value to combine
    :type b: bytes

    :output b: bytes
    """
```

Takes 2 or more bytes arrays of type bytes32 or bytes and combines them into one.

sha3/ keccak256

```
def sha3(a) -> b:
    """
    :param a: value to hash
    :type a: either str_literal, bytes, bytes32

    :output b: bytes32
    """
```

Returns `keccak256` (Ethereum's sha3) hash of input. Note that it can be called either by using `sha3` or `keccak256`.

method_id

```
def method_id(a) -> b:
    """
    :param a: method declaration
    :type a: str_literal

    :output b: bytes
    """
```

Takes a function declaration and returns its `method_id` (used in data field to call it).

ecrecover

```
def ecrecover(hash, v, r, s) -> b:
    """
    :param hash: a signed hash
    :type hash: bytes32
    :param v:
    :type v: uint256
    :param r: elliptic curve point
    :type r: uint256
    :param s: elliptic curve point
    :type s: uint256

    :output b: address
    """
```

Takes a signed hash and vrs and returns the public key of the signer.

ecadd

```
def ecadd(a, b) -> sum:
    """
    :param a: pair to be added
    :type a: num252[2]
    :param b: pair to be added
    :type b: num252[2]

    :output sum: uint256[2]
    """
```

Takes two elliptical curves and adds them together.

ecmul

```
def ecmul(a, b) -> product:
    """
    :param a: pair to be multiplied
```

(continues on next page)

(continued from previous page)

```

:type a: num252[2]
:param b: pair to be multiplied
:type b: num252[2]

:output product: uint256[2]
"""

```

Takes two elliptical curves and multiplies them together.

extract32

```

def extract32(a, b, type=c) -> d:
    """
    :param a: where 32 bytes are extracted from
    :type a: bytes
    :param b: start point of bytes to be extracted
    :type b: int128
    :param c: type of output
    :type c: either bytes32, num128, or address

    :output d: either bytes32, num128, or address
    """

```

RLPList

```

def _RLPList(a, b) -> c:
    """
    :param a: encoded data
    :type a: bytes
    :param b: RLP list
    :type b: list

    :output c: LLLnode
    """

```

Takes encoded RLP data and an unencoded list of types. Usage:

```

vote_msg: bytes <= 1024 = ...

values = RLPList(vote_msg, [int128, int128, bytes32, bytes, bytes])

var1: int128 = values[0]
var2: int128 = values[1]
var3: bytes32 = values[2]
var4: bytes <= 1024 = values[3]
var5: bytes <= 1024 = values[4]

```

Note: RLP decoder needs to be deployed if one wishes to use it outside of the Vyper test suite. Eventually, the decoder will be available on mainnet at a fixed address. But for now, here's how to create RLP decoder on other chains:

1. send 6270960000000000 wei to 0xd2c560282c9C02465C2dAcDEF3E859E730848761
2. Publish this tx to create the contract:

(continued from previous page)

```
:type a: address
"""
```

Causes a self destruction of the contract, triggers the `SELFDESTRUCT` opcode (0xff). CAUTION! This method will delete the contract from the Ethereum blockchain. All none ether assets associated with this contract will be “burned” and the contract will be inaccessible.

assert

```
def assert(a):
    """
    :param a: the boolean condition to assert
    :type a: bool
    """
```

Asserts the specified condition, if the condition is equals to true the code will continue to run. Otherwise, the `OPCODE REVERT` (0xfd) will be triggered, the code will stop it’s operation, the contract’s state will be reverted to the state before the transaction took place and the remaining gas will be returned to the transaction’s sender.

raw_log

```
def raw_log(a, b):
    """
    :param a: the address of the contract to duplicate.
    :type a: * (any input)
    :param b: the name of the logged event.
    :type b: bytes
    """
```

Emits a log without specifying the abi type, with the arguments entered as the first input.

create_with_code_of

```
def create_with_code_of(a, value=b):
    """
    :param a: the address of the contract to duplicate.
    :type a: address
    :param b: the wei value to send to the new contract instance
    :type b: uint256 (Optional)
    """
```

Duplicates a contract’s code and deploys it as a new instance. You can also specify wei value to send to the new contract as `value=the_value`.

3.9 Types

Vyper is a statically typed language, which means that the type of each variable (state and local) needs to be specified or at least known at compile-time. Vyper provides several elementary types which can be combined to form complex types.

In addition, types can interact with each other in expressions containing operators.

3.9.1 Value Types

The following types are also called value types because variables of these types will always be passed by value, i.e. they are always copied when they are used as function arguments or in assignments.

Boolean

Keyword: `bool`

A boolean is a type to store a logical/truth value.

Values

The only possible values are the constants `true` and `false`.

Operators

Operator	Description
<code>x not y</code>	Logical negation
<code>x and y</code>	Logical conjunction
<code>x or y</code>	Logical disjunction
<code>x == y</code>	Equality
<code>x != y</code>	Inequality

The operators `or` and `and` apply the common short-circuiting rules.

Signed Integer (128 bit)

Keyword: `int128`

A signed integer (128 bit) is a type to store positive and negative integers.

Values

Signed integer values between -2^{127} and $(2^{127} - 1)$, inclusive.

Operators

Comparisons

Comparisons return a boolean value.

Operator	Description
<code>x < y</code>	Less than
<code>x <= y</code>	Less than or equal to
<code>x == y</code>	Equals
<code>x != y</code>	Does not equal
<code>x >= y</code>	Greater than or equal to
<code>x > y</code>	Greater than

`x` and `y` must be of the type `int128`.

Arithmetic Operators

Operator	Description
<code>x + y</code>	Addition
<code>x - y</code>	Subtraction
<code>-x</code>	Unary minus/Negation
<code>x * y</code>	Multiplication
<code>x / y</code>	Division
<code>x**y</code>	Exponentiation
<code>x % y</code>	Modulo
<code>min(x, y)</code>	Minimum
<code>max(x, y)</code>	Maximum

`x` and `y` must be of the type `int128`.

Unsigned Integer (256 bit)

Keyword: `uint256`

An unsigned integer (256 bit) is a type to store non-negative integers.

Values

Integer values between 0 and $(2^{256}-1)$.

Note: Integer literals are interpreted as `int128` by default. In cases where `uint256` is more appropriate, such as assignment, the literal might be interpreted as `uint256`. Example: `_variable: uint256 = _literal`. In order to explicitly cast a literal to a `uint256` use `convert(_literal, 'uint256')`.

Operators

Comparisons

Comparisons return a boolean value.

`x` and `y` must be of the type `uint256`.

Arithmetic Operators

`x` and `y` must be of the type `uint256`.

Bitwise Operators

Operator	Description
<code>bitwise_and(x, y)</code>	AND
<code>bitwise_not(x, y)</code>	NOT
<code>bitwise_or(x, y)</code>	OR
<code>bitwise_xor(x, y)</code>	XOR
<code>shift(x, _shift)</code>	Bitwise Shift

`x` and `y` must be of the type `uint256`. `_shift` must be of the type `int128`.

Note: Positive `_shift` equals a left shift; negative `_shift` equals a right shift. Values shifted above/below the most/least significant bit get discarded.

Decimals

Keyword: `decimal`

A decimal is a type to store a decimal fixed point value.

Values

A value with a precision of 10 decimal places between -2^{127} and $(2^{127} - 1)$.

Operators

Comparisons

Comparisons return a boolean value.

Operator	Description
<code>x < y</code>	Less than
<code>x <= y</code>	Less or equal
<code>x == y</code>	Equals
<code>x != y</code>	Does not equal
<code>x >= y</code>	Greater or equal
<code>x > y</code>	Greater than

`x` and `y` must be of the type `decimal`.

Arithmetic Operators

`x` and `y` must be of the type `decimal`.

Address

Keyword: `address`

The address type holds an Ethereum address.

Values

An address type can hold an Ethereum address which equates to 20 bytes or 160 bits. It returns in hexadecimal notation with a leading `0x`.

Members

Member	Description
<code>balance</code>	Query the balance of an address. Returns <code>wei_value</code> .
<code>codesize</code>	Query the code size of an address. Returns <code>int128</code> .

Syntax as follows: `_address.<member>`, where `_address` is of the type `address` and `<member>` is one of the above keywords.

Unit Types

Vyper allows the definition of types with discrete units e.g. meters, seconds, wei, These types may only be based on either `uint256`, `int128` or `decimal`. Vyper has 3 unit types built in, which are the following:

Note: Two `timedelta` can be added together, as can a `timedelta` and a `timestamp`, but not two `timestamps`.

Custom Unit Types

Vyper allows you to add additional not-provided unit label to either `uint256`, `int128` or `decimal`.

Custom units example:

```
# specify units used in the contract.
units: {
    cm: "centimeter",
    km: "kilometer"
}
```

Having defined the units they can be defined on variables as follows.

Custom units usage:

```
a: int128(cm)
b: uint256(km)
```

32-bit-wide Byte Array

Keyword: `bytes32` This is a 32-bit-wide byte array that is otherwise similar to byte arrays.

Example:

```
# Declaration
hash: bytes32
# Assignment
self.hash = _hash
```

Operators

Keyword	Description
<code>len(x)</code>	Return the length as an integer.
<code>sha3(x)</code>	Return the sha3 hash as <code>bytes32</code> .
<code>concat(x, ...)</code>	Concatenate multiple inputs.
<code>slice(x, start=_start, len=_len)</code>	Return a slice of <code>_len</code> starting at <code>_start</code> .

Where `x` is a byte array and `_start` as well as `_len` are integer values.

Fixed-size Byte Arrays

Keyword: `bytes`

A byte array with a fixed size. The syntax being `bytes[maxLen]`, where `maxLen` is an integer which denotes the maximum number of bytes.

Strings

Fixed-size byte arrays can hold strings with equal or fewer characters than the maximum length of the byte array.

Example:

```
exampleString = "Test String"
```

Operators

Keyword	Description
<code>len(x)</code>	Return the length as an integer.
<code>sha3(x)</code>	Return the sha3 hash as <code>bytes32</code> .
<code>concat(x, ...)</code>	Concatenate multiple inputs.
<code>slice(x, start=_start, len=_len)</code>	Return a slice of <code>_len</code> starting at <code>_start</code> .

Where `x` is a byte array while `_start` and `_len` are integers.

3.9.2 Reference Types

Reference types do not fit into 32 bytes. Because of this, copying their value is not as feasible as with value types. Therefore only the location, i.e. the reference, of the data is passed.

Fixed-size Lists

Fixed-size lists hold a finite number of elements which belong to a specified type.

Syntax

Lists can be declared with `_name: _ValueType[_Integer]`. Multidimensional lists are also possible.

Example:

```
#Defining a list
exampleList: int128[3]
#Setting values
exampleList = [10, 11, 12]
exampleList[2] = 42
#Returning a value
return exampleList[0]
```

Structs

Structs are custom defined types that can group several variables.

Syntax

Structs can be accessed via `struct.argname`. **Example:**

```
#Defining a struct
exampleStruct: {
    value1: int128,
    value2: decimal
}
#Accessing a value
exampleStruct.value1 = 1
```

Mappings

Mappings in Vyper can be seen as [hash tables](#) which are virtually initialized such that every possible key exists and is mapped to a value whose byte-representation is all zeros: a type's default value. The similarity ends here, though: The key data is not actually stored in a mapping, only its `keccak256` hash used to look up the value. Because of this, mappings do not have a length or a concept of a key or value being "set".

It is possible to mark mappings `public` and have Vyper create a getter. The `_KeyType` will become a required parameter for the getter and it will return `_ValueType`.

Note: Mappings are only allowed as state variables.

Syntax

Mapping types are declared as `_ValueType[_KeyType]`. Here `_KeyType` can be almost any type except for mappings, a contract, or a struct. `_ValueType` can actually be any type, including mappings.

Example:

```
#Defining a mapping
exampleMapping: decimal[int128]
#Accessing a value
exampleMapping[0] = 10.1
```

Note: Mappings can only be accessed, not iterated over.

3.9.3 Initial Values and None

In Vyper, there is no `null` option like most programming languages have. Thus, every variable type has a default value. Nevertheless Vyper has the option to declare `None` which represent the default value of the type. Note that there is no option to assign `None` when initiating a variable. Also, note that you can't make comparisons to `None`. In order to check if a variable is empty, you will need to compare it to its type's default value.

Here you can find a list of all types and default values:

Table 1: Default Variable Values

Type	Default Value
bool	False
int128	0
int256	0
uint256	0
decimal	0.0
address	0x00
bytes	32 \x00

Note: In `bytes` the array starts with the bytes all set to `'\x00'`

Note: In reference types all the type's members are set to their initial values.
